Bilateral multiple renal arteries: A case report

A Mishra*, PK Sharma1, P Manik1, PP Mishra1

Abstract

Introduction

Knowledge of renal artery variations is important because of increasing number of surgical and radiological interventions in the region of the kidney. Usually the renal artery arises from the lateral aspect of abdominal aorta below the origin of superior mesenteric artery at the upper lumbar level. It divides into anterior and posterior divisions close to the hilum of the kidney, which give rise to a number of end arteries known as segmental arteries supplying the respective segments of the kidney. While an accessory RA is the one that is accessory to the main RA supplying the kidney.

Discussion

Commonly reported variation regarding renal arterial vasculature is presence of an accessory renal artery along with the main renal artery. But the number of total renal arteries more than three or four is less frequently reported. Embryologically the accessory renal arteries represent the persistence of foetal arteries supplying the developing kidneys.

Conclusion

Presence of multiple renal arteries is of profound clinical importance because of increasing number of surgical and radiological intervention in the renal hilar area. Moreover there is gradual preference towards the minimally invasive surgeries. So knowledge of these variations should be kept in mind prior to intervention in this area.

Case report

We report a case of an 18 yr old female, having five renal arteries, three on the right side and two on the left side found on the CT Aniographic image analysis. All of them originated opposite to the body of the L1 vertebra from the aorta in close approximation and entered the substance of the kidney through the hilum.

Figure 1: showing three renal arteries (numbered 1,2 and 3) on the right side supplying right kidney and originating from abdominal aorta note that the 2nd renal artery is crossing third renal artery from front.

visible arteries entering the kidneys, their vertebral level of origin was observed and noted in sagittal maximum intensity projection (MIP) images as well as in volume rendered images. Also the length and diameter of the arteries was measured with the help of an electronic caliper.

While performing the study, on analysis of angiographic images of an eighteen years old female we observed that there were three renal arteries supplying the right kidney (Figure 1). All of them were originated from abdominal aorta opposite the L1-vertebra in close approximation and entered the kidney through the hilum. The second renal artery was crossing the third renal artery from the front while passing to the hilum (Figure 1).

On observing the left side we found that the left kidney was supplied by two renal arteries (Figure 2). Both the arteries were given off by the abdominal aorta opposite the L1 – vertebra in close approximation and entered the kidney from the hilum. We measured the length and diameter of the arteries and analysed their branching pattern. If the artery divided before reaching the hilum of the kidney then it was labelled as prehilar branching. The observations regarding these arteries are shown in table 1.

**Discussion**

During embryological development as the kidneys ascend from the pelvis to the vertebral level, they receive their blood supply from the vascular structures close to them. Initially renal arteries are the branches of common iliac arteries.

Later, while the kidneys ascend they receive new branches from the aorta, and the inferior branches disappear. In the ninth week of the intrauterine life the kidneys come into contact with the suprarenal glands and the ascent stops. The kidneys receive their most cranial branches from the aorta. These are the permanent renal arteries². Persistence of the foetal arteries; present in adults as accessory renal arteries. In recent times, minimal invasive surgery is preferred in all surgical branches to decrease morbidity. Despite refinement in surgical techniques in the field of urology like laparoscopic procedures; vascular complications still accounts for considerable morbidity and mortality. Small diameter (less than 3 mm) accessory vessels are often not relevant to graft function and can be sacrificed but can cause unexpected bleeding from accidental transaction. Such bleeding is a potentially serious complication of laparoscopic surgery. The same can require conversion of a laparoscopic procedure to an open procedure³. To avoid these complications the knowledge of renal vasculature is mandatory prior to any surgical intervention.

Presence of the accessory renal artery (ARA) is the most common and clinically important variation of the renal artery. The ARA arises as a separate branch from the aorta or iliac artery, and it has been reported with a prevalence of approximately 25–30% different study groups⁴.⁵. According to Novic et al. there is no definite limit to the number of accessory renal arteries; although more than three on the same side seems to be very rare⁶. Rossi et al. reported a case with seven renal arteries while Kinnunen et al. reported another case with ten additional renal arteries⁷.⁸. Miclaus and Matusz described a rare case with eight renal arteries (bilateral quadruple) as revealed by routine multidetector computed tomography angiography⁹.

Ogeng’o et al. studied the trajectory of renal arteries. Out of all double renal arteries they found; 59.5% were parallel, 21.4% overlapped, 11.9% were divergent and 7.1% crossed¹⁰. We also report crossing of the renal arteries on the left side.

**Conclusion**

The knowledge of renal angioarchitecture, whether usual or variant, is considered to be a prerequisite for
